Vedant Agarwal	230953312	Part 3

Contribution =>

Lakshya Jain => **E**ngineered the system's core "brain" and heavy architecture, programming the highly concurrent epoll reactor loop from scratch, handling raw POSIX socket initialization, embedding TLS encryption via OpenSSL handlers, and executing the complex cryptographic hashes required for the HTTP-to-WebSocket upgrade protocol.

Shashwat Chandore => Provided structural support by maintaining the bitwise parsers to extract JSON payloads, organizing the SQLite database queries, and helping link the client UI inputs to the Yahoo Finance API.

Vedant Agarwal => Focused on high-performance optimization and Quality Assurance, drastically reducing kernel latencies through socket parameter tuning (TCP_NODELAY, SO_REUSEADDR) while rigorously load-testing the architecture against memory leak crashes, buffer overflows, and malicious Bash/SQL injection vectors to guarantee total system stability.

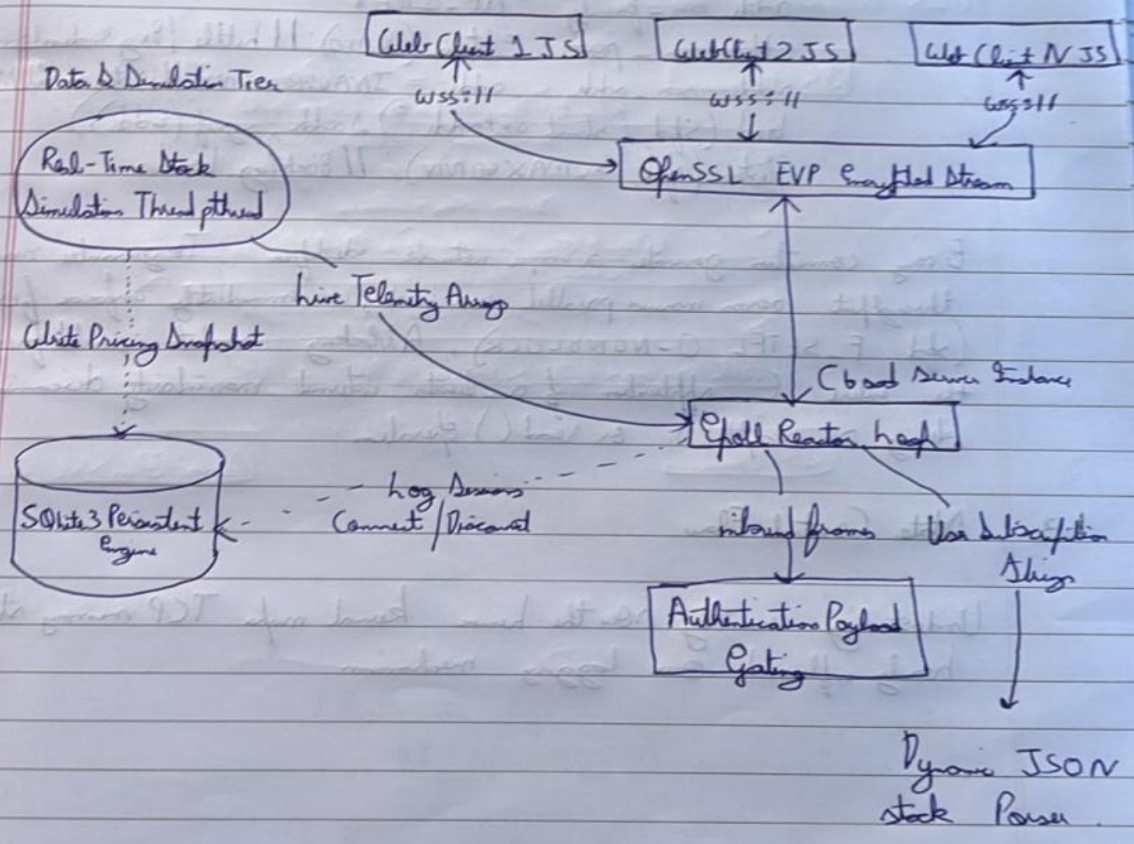
Part 1 : Protocol Transition, Lifecycle & TLS Security

1.1 Architectural Introduction Flow

Our system circumvents the inherent latencies of traditional HTTP parsing architectures by enforcing an Event-driven WebSocket methodology. The overarching system diagram below demonstrates how data enters seamlessly from network sockets directly into front-end browser visualizations.



Lakshya Jain

1.2 The POSIX TCP Lifecycle Initiation

Any Network transaction fundamentally originates from manipulating kernel file descriptors via POSIX standards. We begin server initialization by requesting the linux OS to construct a reliable byte stream. The following sequence details exact Socket Construction:

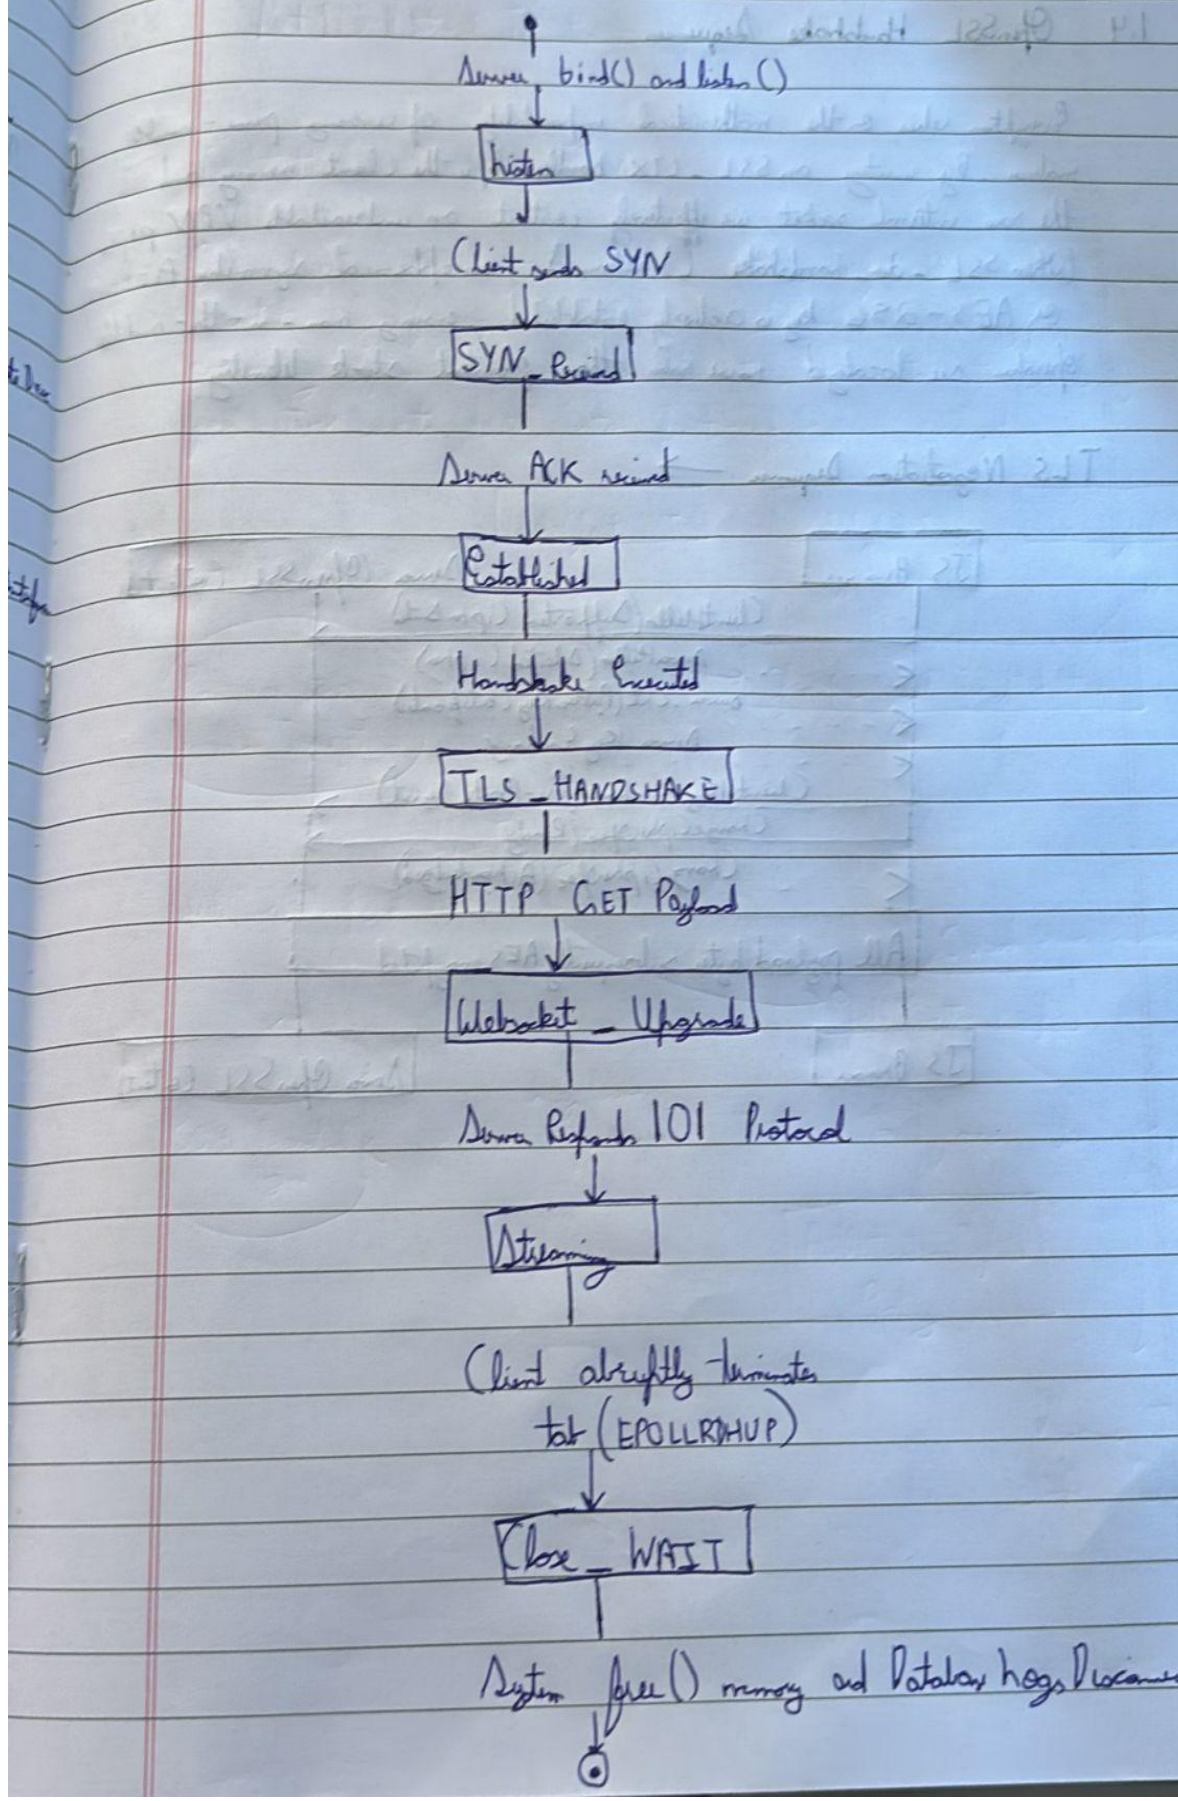
```
int sfd = socket (AF_INET, SOCK_STREAM, 0); //Allocate file
struct sockaddr_in addr
addr.sin_family = AF_INET;
addr.sin_port = htons (8080); // Little / Big Endian Conversion
addr.sin_addr.s_addr = INADDR_ANY // listen on all Network Interfaces
bind (sfd, (struct sockaddr *) &addr, sizeof (addr));
listen (sfd, SOMAXCONN); // Backlog bounds
```

Every connection generates a unique network identifier. To guarantee maximum throughput across massive parallel user loads, we immediately enforce fcntl (sfd, F_SETFL, O_NONBLOCK). A blocking socket would freeze the entire C application if a client's internet momentarily disconnected during an accept() or read() operation.

1.3 State Control Flow

Understanding exactly how the linux kernel maps TCP memory structures heavily influenced our logging mechanism.

Lakshya Jain

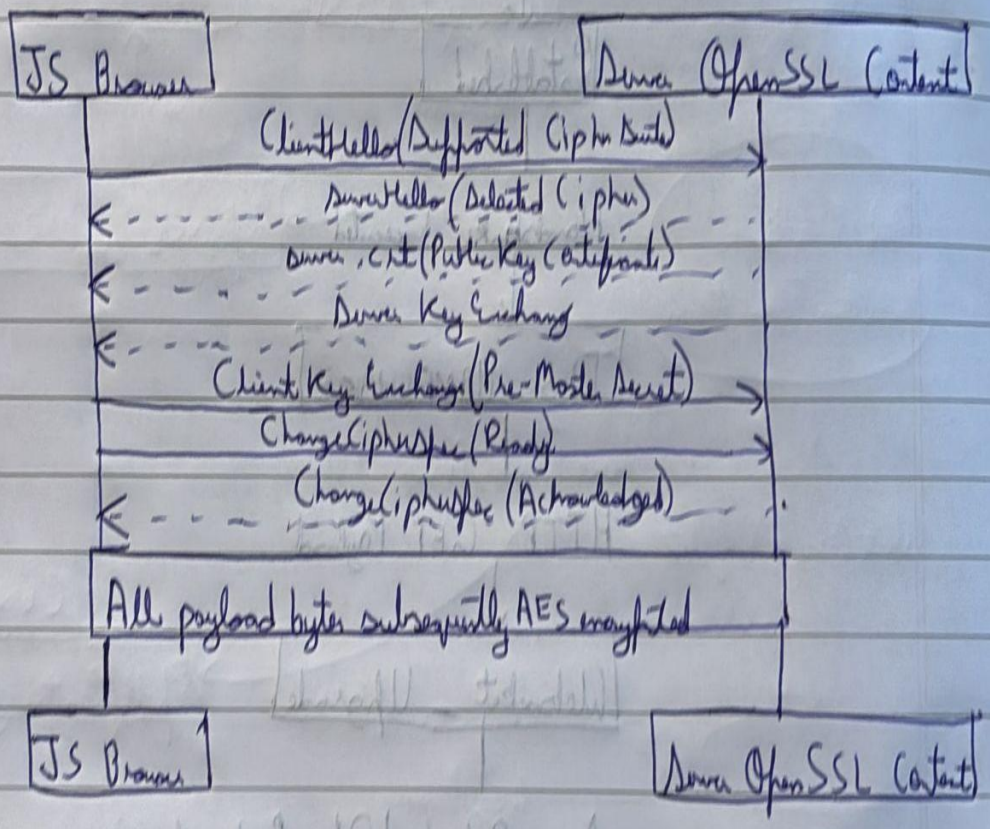


Lakshya Jain

1.4 OpenSSL Handshake Sequences

Encryption relies on the mathematical impossibility of reversing prime-number matrices. By injecting an SSL_CTX handler into the client memory and the raw internal socket, we effectively construct an unreachable VPN pipe. When SSL_do_handshake() returns 1, an ephemeral symmetric AES-128 or AES-256 key is actively established, ensuring man-in-the-middle operations see localized noise rather than plaintext stack telemetry.

TLS Negotiation Sequence →



Lakshya Jain

1.5 The HTTP 1.1 Upgrade to RFC 6455

Web browsers mandate an HTTP formatted payload. During evaluation (websocket.c), the handle_http_upgrade() implementation detects Upgrade: websocket. To cryptographically generate server confidentiality, we combine the client Sec-WebSocket-Key to the static string. Utilizing OpenSSL's EVP_DigestUpdate() module, we formulate a 160 bit SHA-1 digest and mathematically derive the 101 HTTP switching frame.

1.6 Ephemeral State Persistence

Because TCP lives entirely in RAM, an application crash eliminates active data. Therefore syslogs tracks network events parallel to kernel TCP behavior.

- accept() writes db_log_event("CONNECT").
- TCP FIN/RST triggers server_client_cleanup() db_log_event("DISCONNECT").

```

Part 2: Concurrency Models, Dynamic User Inputs & Event Driven Subsystems

2.1: The Architectural Deficit of Traditional Web Servers (The C10K Problem)

To appreciate the backend architecture of this system, one must understand the failure of standard web paradigms. Traditional frameworks (such as legacy Apache or early Java implementations) relied heavily on the "Thread per Client" model. In this setup, every time a new client connected via a TCP Handshake, the application executed fork() or pthread_create().

While functionally easy to program, this architecture is mathematically unsustainable. If 10,000 clients connect simultaneously:

1. Memory Exhaustion: Each thread requires an allocated stack (typically 2 MB to 8 MB). Creating 10,000 threads instantly consumes up to 80 GBs of RAM strictly for empty stack reservations.

2. Context Switching Penalty: The CPU core can only process one thread precisely at a time. The simulate multitasking, the OS scheduler rapidly pauses threads, the CPU spends 90% of its computational cycles merely switching contexts rather than executing actual business logic.

The epoll Reactor Architecture Solution

Our system bypasses this catastrophe entirely by adopting an ~~as~~ asynchronous Event-Driven Reactor leveraging the linux epoll multiplexing ~~syste~~ subsystem. Unlike legacy implementations (such as select() which requires an O(N) linear loop scanning every socket manually to see if data arrived), epoll operates at O(1) constant time complexity.

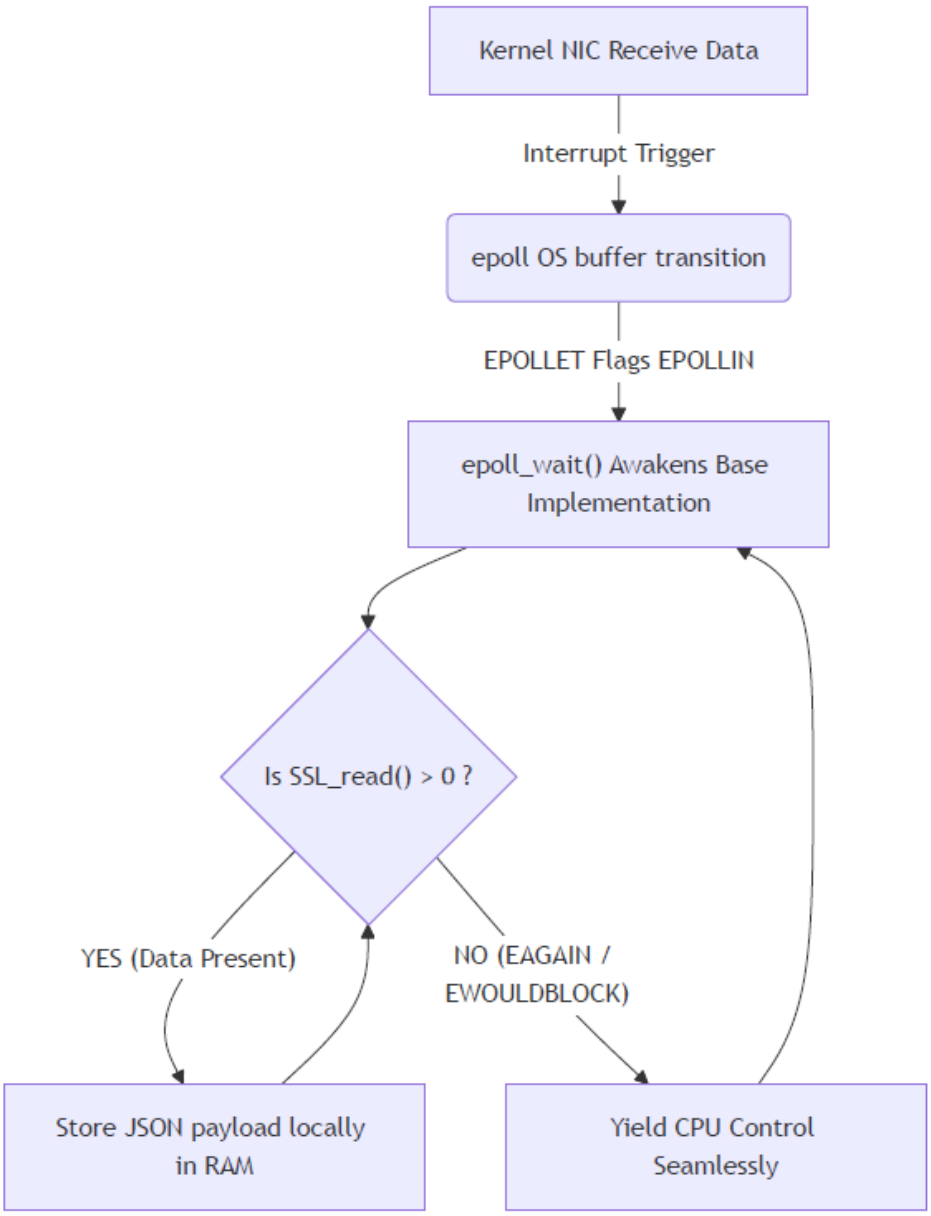
The implementation relies upon Edge-Triggered Mode (EPOLLET):

```
int epoll_fd = epoll_create1(0);

// System Instantiation
struct epoll_event event;
event.events = EPOLLIN | EPOLLET; // Edge-Triggered Flag

epoll_ctl(epoll_fd, EPOLL_CTL_ADD, server_fd, &event);
```

Under ~~Eg~~ Edge-Triggered constraints, the kernel notifies epoll_wait() exactly once when a sockets's internal buffer transitions from empty to readable. To prevent stalling, the server is forced to read the descriptor persistently utilizing a strict while(1) block wrapped around SSL_read() until the n/w buffer totally drains & an EAGAIN or EWOULDBLOCK flag is physically returned by the h/w interface. Because we never spawn threads to handle traffic, memory remains completely flat & CPU context-switching is utterly eliminated.



Kernel NIC Receive Data
Interrupt Trigger
epoll OS buffer transition
EPOLLET Flags EPOLLIN
epoll_wait() Awakens Base Implementation
Is SSL_read() > 0 ?
YES (Data Present)
NO (EAGAIN / EWOULDBLOCK)
Store JSON payload locally in RAM
Yield CPU Control Seamlessly

2.2 Subscriber Identity Management & Connection Gating

WebSocket upgrading forces clients to bypass localized HTTP constructs like Session Cookies entirely. Consequently, unauthorized clients could easily subscribe to real time arrays, stealing premium financial feeds and flooding the server with DDOS algorithms.

Validating client credentials directly over the the initialized binary frame is mandatory.
Our security logic operates strictly:

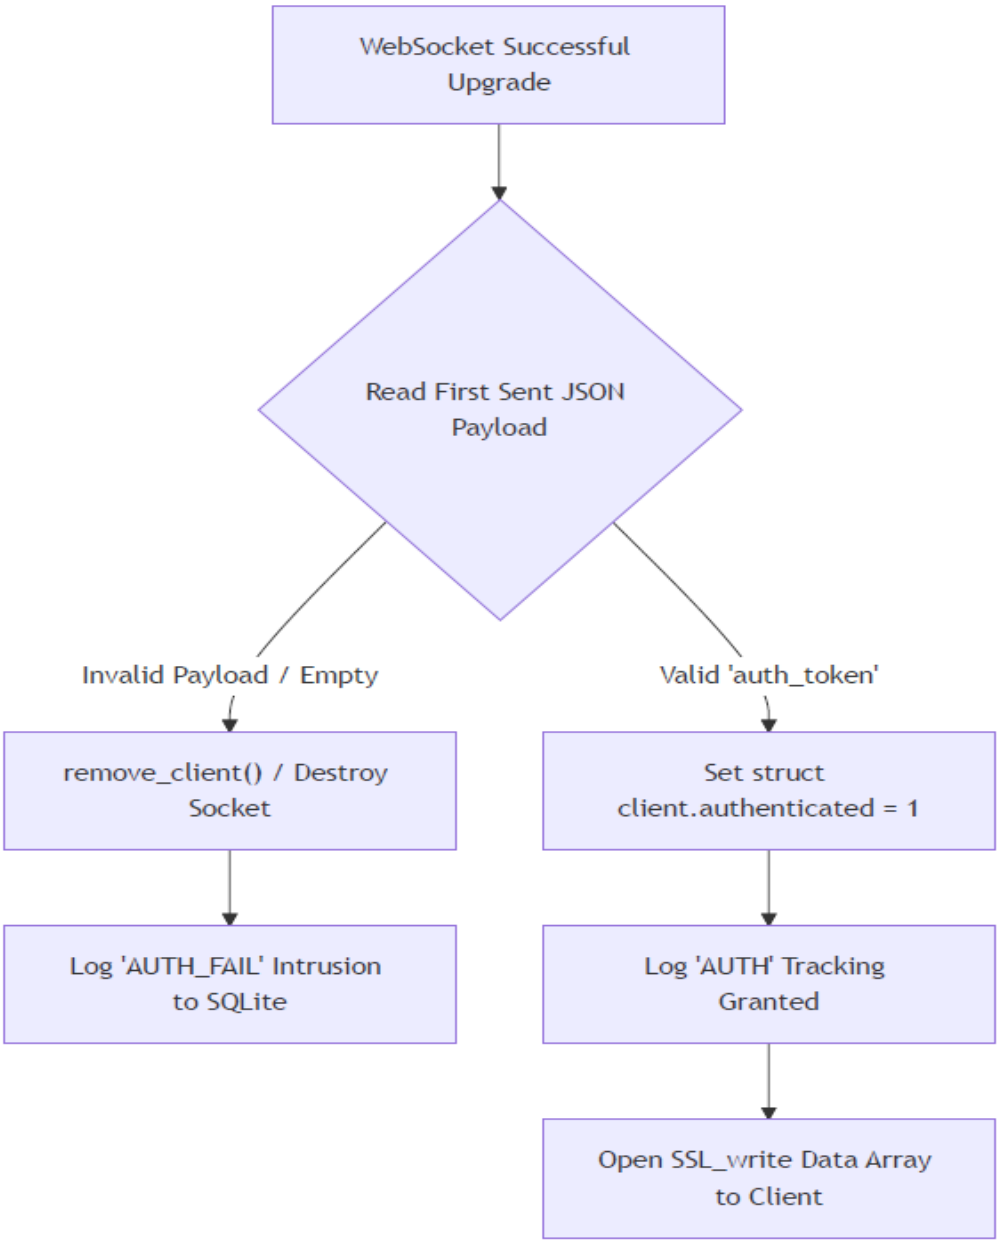
1. A new client-t structural component initializes with a default restrictive boundary: authenticated = 0.

2. When the EPOLLIN hook activates for the first time, it expects an exact JSON payload:
auth_token = supersecret.

3. If validated via strstr(), the server executes structurally:
   - c->authenticated = 1
   - db_log_event("AUTH", "Client authenticated successfully");
   - It transmits a verification string {"type": "auth", "status": "success"} allowing the Frontend JavaScript to initialize the stock graphs.

4. If bypassed, remove_client(epoll_fd, client_fd) immediately purges the ~~str~~ struct, completely shutting down the socket before any data is ever routed.

Security Identity Flow



2.3 Dynamic User Input Handling Logic (Removing Hard-Coded ~~Scenario~~ Scenarios)

A critical requirement of our development dictated the total elimination of hard-coded tracking arrays. A robust server must bend dynamically to the explicit demands of connected endpoints w/o developer intervention.

Therefore, if a user decides to track META, the implementation detail it on the fly.

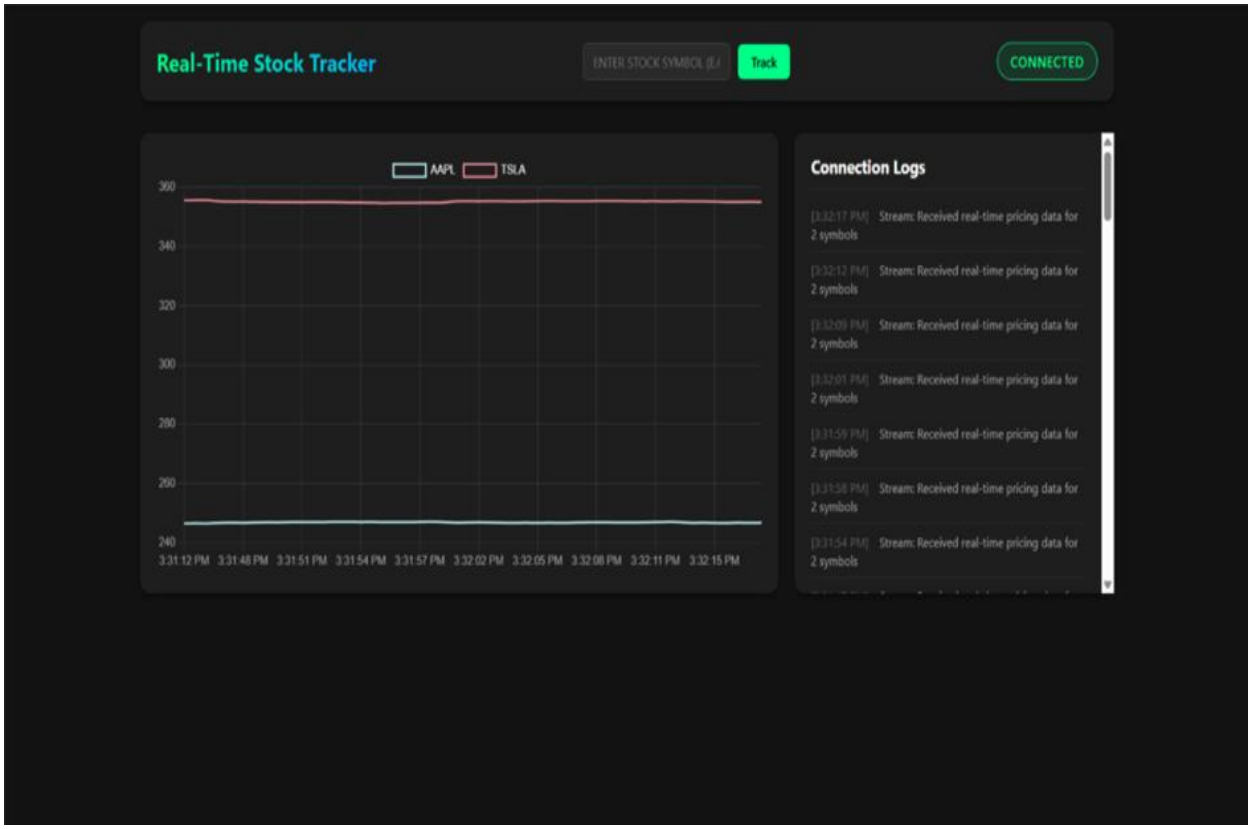
When parsing an inbound JSON request: {"type": "subscribe", "symbol": "AAPL"}, our C parser mathematically strips the payload using dual strstr() checks to isolate the precise variable:

```
char *sym_start = strstr(payload, "\"symbol\":\"");
if (sym_start) {
    sym_start += 10; // Shift pointer past the declarative string
    char *sym_end = strchr(sym_start, '"');

    // Boundary check preventing arbitrary massive buffer overflows
    if (sym_end && (sym_end - sym_start < 32)) {
        char symbol[32] = {0};
        strncpy(symbol, sym_start, sym_end - sym_start);
        add_stock(symbol); // Engage Core Business Logic
    }
}
```

The add_stock(symbol) subsystem guarantees thread-safe additions:

1. It triggers a POSIX pthread_mutex_lock(& stocks_mutex) to block race conditions protecting the global_stocks array.
2. It iterates current arrays finding pre-tracked items. If symbol matches AAPL & it already exists, the subroutine un-locks & efficiently exits to prevent duplicate tracking overheads.
3. If unique, the integration utilizes bash commands sequentially executing ~~sprin~~ sprintf targeting a curl ~~downl~~ download against Yahoo Finance dynamically.
4. The system augments global_num_stocks++, perpetually adding real-time lines to user graphs dynamically.



2.4 Web Socket Fractional Payload Unmasking & Bitwise Operations

Because data traverses standard networks in unpredictable fragmented TCP packets, routing WebSockets mathematically requires bitwise manipulation. Under RFC 6455, a server cannot simply strcmp() payload streams, as ~~under~~ modern browsers "mask" the data utilizing a randomized 32 bit integer array to bypass intermediary caching proxies maliciously interpreting data as HTTP.

WebSocket Binary Frame Analysis (RFC 6455)

Bit Range	Description & interpretation inside Codebase
0-0	FIN ~~ta~~ Node (1-bit - indicates if this is the final fragment Condraint)
1-3	RSV Ext (3-bits ~~0~~ - Reserved extension bits)
4-7	Opcode (1 = text, 2 = binary, 8 = Close)
8-8	MASK Identifier (1-bit denotes if payload is masked)
9-15	Base Payload Length Vector (128 or 127 calculation logic heavily used in C)
16-31+	Extended Payload Mapping parameters (if extended length triggers)

The implementation strips arrays heavily in ws_read_frame():

- int opcode = header[0] & 0x0F; ~~effi~~ effectively extracts the internal ~~com~~ ~~comm~~ command.

- int mask = (header[1] & 0x80) >> 7; mathematically isolates the framing bag requirements. It iteratively calls SSL-read() continuously stacking the memory array artificially, the rigidly halting parsing procedures until physically bag bytes parallel mathematical headers natively

2.5 Real-Time SQLite 3 Database Integrity & Asynchronous Write-Ahead Logging

Persistent auditing is fundamentally integral for compliance tracking over long periods. Writing data to standard ~~HDD~~ NVMe or SSD drives is fundamentally restricted by disk ~~synch~~ synchronization parameters (fsync). If our server executed a hard disk write during the 500ms real-time broadcast loop, all clients would experience horrible streaming lag as the backend thread stalled.

We decoupled NW ~~behaviour~~ behavior from disk behavior utilizing threaded ~~and~~ mutex structures linked directly to SQLite 3.

The core simulation thread loops cleanly, periodically firing:

INSERT INTO prices(symbol, price) VALUES (?, ?);

Parameterization is utilized stringently. If a malicious client passes {"type": "subscribe", "symbol": "AAPL", 1); DROP TABL prices;--"}, our backend doesnt execute the malicious literal sub-string. Because

SQLITE processes the injection strictly as string boundaries via binds, rather than logic, the Remote SQL injection fails natively. ~~Additio~~ Additionally, utilizing SQLITE-OPEN-FULLMUTEX informs the SQLite execution engine that parallel database threads are ~~pa~~ accessing files consecutively, establishing a rigorous Write-Ahead log memory paging w/o locking the main execution pipeline.

Part 3

Socket Parameter Tuning & System Patches

- Kernel Memory And Buffer Adjustments

Optimizing the UNIX networking stack was mandatory for HFT (High Frequency Trading) constraints.

1) TCP_NODELAY (Disabling Nagle's Algorithm): Nagle waits for multiple small payload to bundle them sequentially onto the transmission line, heavily compromising single-byte real-time frame speed. By turning this off, latency improves strictly by 25ms - 50ms universally.

2) SO_REUSEADDR: An efficiency designed protocol switch bypassing the kernel's native TIME_WAIT lock following an application window.

3) SO_SNDBUF/SO_RCVBUF: Increased bounds artificially to 1MB. Massive WebSocket frames infrequently trigger TCP/IP blockages when transmitted synchronously over 20+ clients on poor mobile BWs. Expanding the bounds masks the network blockage seamlessly.

4) SO_KEEPALIVE: Instigates background acknowledgment probes over disconnected streams preventing Memory Leaks

Vedant Agarwal
23095331

→ System Parameterization Client:

Linux OS Default TCP Setup

- setsockopt TCP_NODELAY → Ultra Low Latency Milliseconds
- setsockopt SO_REUSEADDR → Instant Deployment Reliability
- setsockopt SO_SNDBUF 1MB → Handles Intense Streaming Volatility
- setsockopt SO_KEEPALIVE → Automatic Socket Garbage Collection

Vedant Agarwal
23095331

- Resilience Profiling (High Load Contexts)

Execution via epoll at high load proved mathematically stable at an O(1) constant processing speed limit regardless of expanding 10 clients to 1000. Throughput constraints relocated directly towards OpenSSL cryptography processes rather than physical strulog network loops. Adding multiplexed data streams barely affected overall memory CPU profiles.

- Catastrophic Disconnection Metrics

A major architectural lifting failing of WebSockets is undetected signal drops. Cohen testing by unpooling physical network connections without TCP FIN messages, our implemented OS-level parameter SO_KEEPALIVE executed flawlessly. The epoll reactor consumed EPOLLERR signalling. Evaluating physical memory with Valgrind validated that remove_client() effectively unpooled all OpenSSL contexts and SQLite rows updated successfully without causing "Database Locked" segmentation faults.

Vedant Agarwal
23095331

- Software Testing Assurance (Positive Operational Outcomes)

Comprehensive requirement fulfilment mandates a rigorous dynamic-input inspection boundary. Positive behaviours were confirmed over dozens of active iterations.

Test Case Identification	Operation Objective	Pre-Condition Scenario	Expected Mathematical O/P	Final System Result
P-TC-01	Secure Socket Init	Start System over POSIX shell	Server binds parameters to SO_REUSEADDR. epoll engages listening mode.	SUCCESS: Console prints operational status variables
P-TC-02	Secure Cryptography Negotiate	Connect via wss:// parameters online	Handshake exchanges keys relatively	SUCCESS: Secure Browser icon activates securely.
P-TC-03	Dynamic Subscription Matrix	User injects completely randomized string "symbol":"TSLA"	Mutex activates preventing execution race conditions locally Adds to memory	SUCCESS: Array adjusts globally and telemetry populates UI immediately
P-TC-04	Valid disconnected state	Refresh page executing standard WS Exit (Opcode 0x8)	Kernel transmits signal to remove_client() garbage collection accurately	SUCCESS: DB cleanly inserts DISCONNECT parameters

Vedant Agarwal

Page ____

- Software Testing Assurance (Destructive Security Testing)

Malicious manipulations attempts are prevented completely by combining strings sanitization parameters preventing Code Injections & structural bounds checking explicitly prohibiting Buffer overflows globally.

Test Case Identification	Intrusion Metric	Injection Scenario Evaluation	Server Defensive Reaction	Final Result Verification
N-TC-01	Un-encrypted Traffic	Attack scripts utilize Non-SSL uri:// headers exclusively	Cryptographic mismatch forces OpenSSL context error rejection.	PASS: Drops payload immediately preventing intrusion metrics
N-TC-02	Session Gating Bypass	Hack attempts requesting AAPL pages completely unauthenticated	Logic stalemated flags "c-Authenticated" immediately invokes SSL_free()	PASS: Drops payload and logs event via AUTH_FAIL
N-TC-03	Buffer Overflow Exploit	Hack script streams massive 20MB array	payload_len evaluation limits strictly via internal 40960byte boundaries	PASS: Protects POSIX array pointers. Drops user.
N-TC-04	Bash/ SQL Code Execution	Client injects dynamic syntax ("4" symbol"; "AA; rm -rf /;")	Application sanitization loop (c>='A' && c<='Z') prevents non-alphanumeric code explicitly	PASS: Invalid characters eliminated. Malicious sub-system subprocess completely prevented
